Clinical Scenario: You have a patient that looks very ill, is febrile and hypotensive. You astutely recognize he is in septic shock. You send off all the appropriate studies and begin early goal directed therapy. However despite aggressive fluid administration and the use of several catecholamines his MAP remains below 65. If only there was some super drug out there that could help correct all this...

P: In patients presenting in vasodilatory septic shock

I: Does the use of vasopressin

C: In addition to the current standard of care

O: Help improve patient morbidity and or mortality

Quick Review:

Donald Landry (1990's) noted profound hypotension in a patient with bleeding varices with discontinuation of vasopressin. Patient was in septic shock. Further studies showed patients in septic shock had increased pressor sensitivity to vasopressin and had a deficiency of vasopressin. Vasopressin acts on V1a receptors to potentially constrict vascular smooth muscle.

Emanuel Rivers (2001) – Early goal directed therapy to optimize cardiac preload, afterload, and contractility. First 6 hours aggressive fluid administration, vasopressors, pRBC transfusions and dobutamine to establish CVP 8-12, MAP 65-90, ScvO2 >70%, HCT >30%

Surviving Sepsis Campaign (2008) – “We recommend either norepinephrine or dopamine as the first choice vasopressor agent...” “We suggest that epinephrine, phenylephrine, and vasopressin should not be administered as the initial vasopressor in septic shock. Vasopressin 0.03 units/min may be added to norepinephrine...” “There is no high-quality primary evidence to recommend one catecholamine over another.”

Article	Study Type	Patient Population	Results	Conclusions	Limitations
Russell, James, A., et. al. NEJM 358;9 (Feb 28 2008) 877-887. Vasopressin versus Norepinephrine Infusion in Patients with Septic Shock.	Multi-center, randomized, stratified, double blind trial. Primary outcome - Death from any cause assessed at 28 days after start of infusion Secondary outcome - 90 day mortality; days alive - free of organ dysfunction, vasopressor use, mechanical ventilation,	778 patients from 27 centers Inclusion -Patients >16 yo in septic shock resistant to fluids and requiring low dose NE at least 5 micrograms per minute Drug Infusion Vasopressin at 0.03 U/m NE at 15 microg/m	Death at 28 days 35.4% vs. 39.3% Death at 90 days 43.9% vs. 49.6%, no difference in organ dysfunction SAE 10.3% vs. 10.5% Less severe shock mortality 26.5% vs. 35.7% at 28 days and 35.8% vs. 46.1% at 90 days	No significant difference in 28 day mortality rate No significant difference in 90 day mortality rate No significant difference in SAE Vasopressin allowed rapid lowering on NE infusion while maintaining MAP	Vasopressin levels were not measured to guide dosing or duration of infusion Studied the effects of low-dose vasopressin as a “catecholamine-sparing drug” Mean time from study entry to drug infusion was 12 hours Only low dose

	RRT, SIRS, steroid use; length of stay in ICU and hospital; adverse events		More cardiac arrests occurred in the NE group (8/11) and more digital ischemia in the vasopressin group (8/10)	Observed overall mortality considerably lower than the expected 60% Vasopressin may be more beneficial in less severe septic shock	vasopressin was used Excluded patients with ACS and severe heart failure
Russell, James A., et al. Critical Care Medicine 37;3 (2009) 811-818. Interaction of vasopressin infusion, corticosteroid treatment, and mortality in septic shock	<i>Post hoc</i> sub study of previous VASST trial Primary outcome -28 day mortality Secondary outcome -90 day mortality; days alive and free from organ dysfunction over the first 28 days	VASST trial 589 patients were treated with corticosteroids Inclusion - Same as above Different steroids were used but no statistically significant difference among dosing or type	Death at 28 days 35.9% vs. 44.7% Death at 90 days 45.2% vs. 55.5% With no steroids death at 28 days 33.7% vs. 21.3% Vasopressin + steroids has less organ dysfunction suggested by increased days alive and free from shock, mechanical ventilation, renal failure, and any organ failure Steroids significantly increased vasopressin levels by 33% (6 hours) and 67% (24 hours) Significant higher rate of cardiac death in NE + steroids	Statistically significant decrease in 28 day mortality with vasopressin + steroids In patients not treated with steroids, vasopressin associated with increased mortality Vasopressin decreased total NE dose similarly in steroid vs. non-steroid treated pts Patients treated with steroids had increased severity of illness at baseline	Retrospective study Use of corticosteroids was not randomized, blinded, or controlled Same as previous trial

Bottom Line: I would continue to consider vasopressin as a second line agent in patients presenting in vasodilatory septic shock.

At this time clinical trials have not proven that vasopressin improves mortality and morbidity in adults or children. However, proponents argue that the dose of vasopressin used was ineffective and it was not given quick enough in accordance with EGDT. There is still conflicting evidence whether increasing vasopressin doses result in worsening side effects such as coronary ischemia, ischemic skin lesions, reduced cardiac output, tachyarrhythmia, and splanchnic hypoperfusion. To date pressor catecholamines have never been tested in a well-designed trial but are the current standard of care. Anecdotally, my short experience in the ICU the patients started on norepinephrine + vasopressin seemed to respond better than patients on norepinephrine + phenylephrine.
